## **INTRODUCTION**

---

The U.S. Environmental Protection Agency (EPA) is conducting a remedial investigation and feasibility study for polychlorinated biphenyls (PCBs) in the Upper Hudson River, New York. A number of ecological issues will be evaluated during this process. One area of interest is to understand how PCBs accumulate in aquatic biota. General Electric Company (GE) has contracted with Quantitative Environmental Analysis (QEA) to develop a PCB fate and transport model that includes an aquatic food web component. Another area of interest is to determine what impacts removal of sediment will have on habitat used by aquatic organisms. To date, EPA has not developed site-specific information to evaluate these issues.

To address these issues, GE contracted with Exponent (formerly PTI Environmental Services) to develop and implement a field program to collect relevant site-specific data. In August 1997, a study plan entitled *Ecological Value and Food Web Structure of Aquatic Vegetation Communities of the Upper Hudson River: Study Plan* (the Study Plan) (PTI 1997b) was submitted to New York State Department of Environmental Conservation (NYSDEC) and EPA. The two primary purposes of the study were to investigate the ecological values of the submerged aquatic vegetation (SAV) beds in Thompson Island Pool and to provide site-specific data on the food web structure within Thompson Island Pool and Stillwater. This information will allow evaluation of the impacts that invasive remedial options will have on the aquatic community and to calibrate key components of the food chain model being developed by QEA. This report documents the data collected as part of the vegetation survey, fish community analysis, and the analysis of phytophilous macroinvertebrates (PMI) and benthic macroinvertebrates (BMI). Additional reports will be prepared to document other aspects of the study.

The data presented in this interim report will be used to better understand bioaccumulation processes and the differences in PCB biomagnification in different aquatic food webs. A bioaccumulation model to predict PCBs in pumpkinseed and largemouth bass in the Upper Hudson River is being developed by QEA to compare predicted levels of PCBs to actual PCB concentrations reported for those species collected by NYSDEC as part of the state PCB monitoring program in the Upper Hudson River. Differences in the ratio of PCB concentrations in largemouth bass and pumpkinseed between Thompson Island Pool and Stillwater and differences between predicted and actual PCB concentrations in fish from these two areas suggest that there may be important differences in the supporting food webs between Thompson Island Pool and Stillwater. Data describing fish feeding patterns, trophic relationships in different habitats, and differences in communities between habitats and between Thompson Island Pool and Stillwater will support refinement of the predictive models.

SAV provides habitat for invertebrates and algae consumed by fish, shelter for fish breeding and rearing, food for waterfowl, substrate stabilization, and mitigation of nutrient loading. SAV is most common in areas with low currents, fine sediments, and high organic matter. Because fine sediments typically have a higher total organic carbon (TOC) content, their PCB concentrations are generally higher on a dry-weight basis than those of coarse-grained sediments. The fine-grained sediments, especially in Thompson Island Pool, are therefore the most likely to be dredged as part of EPA's remediation approach. However, because the biological productivity, diversity, and ecological value of SAV habitats is high relative to unvegetated habitats, a remediation design that ignores the ecological value of SAV could result in adverse impacts to important species on the Upper Hudson River.

This report presents all of the results of the study that are available at this time, which include:

- The vegetation survey
- The analysis of food webs and community structure, including:
  - Locations of sampling stations as recorded by the differential global positioning system (DGPS)
  - Fish community analysis
  - Qualitative observations of BMI and PMI.

All data generated during related field activities are reported in the appendices. This report presents a brief discussion of the potential effects of dredging on the distribution and abundance of aquatic habitats in the Upper Hudson River. Additional information about the potential effects of dredging will be evaluated as part of a separate task.

# AQUATIC VEGETATION SURVEY

---

## BACKGROUND

The vegetation survey was conducted by Exponent to provide the basis for quantitative estimates of the distribution of SAV in Thompson Island Pool and determine the maximum depth of SAV occurrence in Thompson Island Pool. The survey was also conducted to provide a context in which to interpret habitat-specific observations of invertebrates and fish and to estimate the significance of these communities to the river in general. The relevant questions identified in the Study Plan address the following:

- The spatial distribution and relative density of the dominant species of aquatic vegetation
- Qualitative relationships between vegetation type, sediment characteristics, and water depth
- Representativeness of habitats at NYSDEC stations for monitoring PCB concentrations in fish
- The depth distribution of the dominant SAV species.

Sampling and analytical methods and survey results are summarized below.

## METHODS

### Sampling

The survey of SAV included the main channel and side channels of the Upper Hudson River from the remnant deposits upstream of Rogers Island to the Thompson Island Dam. The vegetation survey consisted of 104 lateral transects spaced approximately 100 m apart, located from the northern end of Rogers Island to approximately 500 m north of the Thompson Island Dam. The area upstream of Rogers Island was sampled differently because of limitations of sampling equipment, as described below.

Each transect was situated to be approximately perpendicular to the current. At each point along each transect, the vegetation and sediment were observed with a submerged video camera, the water depth was measured using the Hummin digital depth sounder and recorded in field logs, and the vessel position was determined and recorded using DGPS.

Details of the DGPS method for vessel positioning are included in a report by David Evans and Associates, which has been included in Appendix A.

Observations of vegetation species and density, water depth at the point the vegetation was observed, geographic position, and the characteristics of the substrate were recorded at each point along all transects. Only relative vegetation density was recorded according to visual density classes shown in Figure 1. Neither stem density nor biomass per unit area were measured during the vegetation survey. Substrate characteristics were assessed qualitatively, with sediments classified consistently according to five particle size categories: fine (less than or equal to 0.5 mm); sand (0.6–2.0 mm); gravel (2.1–15.0 mm); cobble (15–150 mm); and rock, which consisted of particles greater than 15 cm in diameter, or bedrock. The occurrence of wood was also recorded, but wood particles were not distinguished by size. The total channel width was recorded to an accuracy of 1 m (approximately 1 yd) at each transect using the Bushnell® Yardage Pro™ 400. The time of data collection was recorded at each point, and the distances to shore of the first and last points on each transect were estimated and recorded for all transects.

The original sampling design for the vegetation survey involved spacing points *evenly* along each transect and having only 10 points to a transect. This approach was used from the north end of Rogers Island to the southern end of the island and in the side channel of Rogers Island (transect numbers T1–T19). However this approach resulted in spacing points too widely, such that large areas of vegetated habitat (most common along the river margins) were not being observed, while numerous observations were made in deep areas with no vegetation. After the first half day in the field, the sampling approach was changed so that a higher density of observations would be recorded for each transect. At this time, observations were recorded every 20 ft across the entire transect for transect numbers T20–T32). This method increased the density of observations in the vegetated areas, but also resulted in many observations where there were no plants and was highly time consuming. Finally, observations on transect numbers T33–T104 were spaced 20 ft apart in waters less than or equal to 10-ft deep. One to three points per transect were observed in waters greater than 10-ft deep.

The reach from Hudson Falls to Rogers Island was not surveyed using the same methods as for the rest of Thompson Island Pool. Departure from the standard method was necessary because the DGPS did not receive a positioning signal in the area near the remnant deposits. In addition, the current in this reach was much stronger than in downstream areas. As a result, the video camera could not be positioned properly for SAV observations. Therefore, the observations of vegetation in the reach from Hudson Falls to Rogers Island were made using a hand-drawn map (Appendix A, Figure A-1) and by looking into the water without the aid of a camera. Depth and sediment characteristics were not recorded for most observations in this reach.

## Analysis

Electronic DGPS files of the State plane coordinates of each point on each transect and the observations of vegetation, sediment, and depth were combined in ARC/INFO. Data were plotted to generate maps of the density and distribution of plants in the main channel of Thompson Island Pool. Display maps were created to show the distribution of vascular plants, the distribution of *Vallisneria americana*, and the distribution of algae. Any combination of observations of vegetation can be produced with the existing ARC/INFO database.

The relationship between depth and the presence or absence of vegetation was evaluated statistically. Depth is not, by itself, a truly "controlling factor" in the development of aquatic vegetation. Light availability is more likely to determine the presence or absence of plants in an aquatic system (Harley and Findlay 1994) and will correlate with depth (Sheldon and Boylen 1977). This analysis is focused on the changes in vegetation density, or its presence/absence, with depth.

Because the water fluctuated irregularly, measurements of depth recorded during the vegetation survey were relative, not absolute, depth measurements. These relative depth measurements were standardized to the annual mean depth using hydrologic data generated and maintained by the U.S. Geological Survey. There is a water stage recorder at Fort Edward that records the river's stage height every 15 minutes of every day. These data are posted on the Internet (<http://water.usgs.gov/public/realtme.html>), and summary statistics are published each year. The data providing the stage height at Fort Edward at all time intervals during the vegetation survey, August 7 through August 12, 1997, were downloaded from the Internet. The annual mean discharge for Fort Edward for the period from 1978 to 1995 was reported by USGS (1995) to be 5,095 ft<sup>3</sup>/sec. The annual mean stage height of 21.88 ft for Fort Edward was calculated from this value using a model of the relationship between stage height and discharge derived by USGS (1992). For each data point on each transect, the adjusted depth was calculated as:

$$AD = (G_{AM} - G_T) + D_T$$

where:

- AD = adjusted depth (ft)
- G<sub>AM</sub> = annual mean stage height (ft)
- G<sub>T</sub> = stage height at time T (ft)
- D<sub>T</sub> = depth at time T (ft).

For the statistical analysis of the relationship between the presence of plants and depth, the adjusted depth was used. The possibility of a relationship between vegetation and depth was explored by plotting the frequency of observations of vascular plants at each depth represented by the data. For development of a statistical model, the vegetation density

data were represented in two ways: as a presence/absence variable and as an ordinal variable, with categories of increasing density (i.e., absent, low, medium, and high). A logistic regression was used to evaluate the relationship between the presence of vegetation and depth, regardless of vegetation density. The logistic regression models the probability that vegetation would be present at any given water depth. The form of the logistic regression equation was:

$$P(\text{Presence}) = \frac{\exp(B_0 + B_1 \times \text{depth})}{1 + \exp(B_0 + B_1 \times \text{depth})}$$

where:

P(Presence) = probability that vegetation was observed

B<sub>0</sub> = model intercept

B<sub>1</sub> = depth parameter

depth = adjusted water depth.

A maximum likelihood loss function was used to fit the regression model to the data. The relative contribution of any one explanatory variable to the model was evaluated by the decrease in the loss estimate when another variable was added to the model:

$$(\text{Loss}(M1) - \text{Loss}(M2)) / df$$

where:

Loss = log-likelihood loss value ("Final value or loss function" in SYSTAT output)

M<sub>1</sub> = a given logistic regression model

M<sub>2</sub> = model M<sub>1</sub> with an additional explanatory variable

df = degrees of freedom associated with the additional variable.

The equation defines a goodness-of-fit statistic with an approximate chi-square distribution with df degrees of freedom. This statistic was compared to a chi-square critical value to test if the additional variable improved the fit of the model. For these analyses, df was equal to 1 in all cases. At 95 percent significance with 1 degree of freedom, the chi-square critical value is 3.8. When the loss function decreased by more than 3.8 with the addition of a new variable, that variable significantly improved the goodness-of-fit for that model. SYSTAT was used for all statistical analyses.

To evaluate the effect of depth on vegetation density, the distribution of observations with vegetation present was displayed in a quantile plot. The depths associated with categories of density (absent, low, medium, and high) were also plotted and overlaid in one plot to show the depth limits of each vegetation density. The influence of the sediment size

variable was evaluated by tabulating the numbers of vascular plant observations for each sediment category.

## RESULTS AND DISCUSSION

All data generated for the vegetation survey are presented in Appendix A, and Figures 2 and 3 present all observation points on transects. The aquatic vascular plant species observed were *V. americana*, *Trapa natans*, *Potamogeton epihydrus*, *P. richarsonii*, *P. angustifolium*, *Elodea canadensis*, *Nymphaea odorata*, and *Najas* species. Open sediments covered with a layer of periphyton were common and were recorded generically as an "algal mat." Filamentous algae was also very common, either found growing in large isolated patches or mixed with stems of vascular plants. *V. americana* was the plant most commonly observed throughout the main channel of Thompson Island Pool. *T. natans* was the second most common because of the large patch of *T. natans* in the west channel of Griffin Island. Only one other patch of *T. natans* was observed in the Thompson Island Pool, located near the north opening of the Thompson Island navigational channel that runs on the east side of Thompson Island. *T. natans* was not generally distributed in Thompson Island Pool.

Figures 4 and 5 show the locations of vascular plant observations and the densities of the vascular plants observed, and Figures 6 and 7 show the distribution and densities of periphytic algae and filamentous algae. The distribution and density of only *V. americana* is shown in Figures 8 and 9. The distribution and densities of all vascular plants other than *V. americana* are shown in Figures 10 and 11, illustrating the relatively low abundance of species other than *V. americana* in Thompson Island Pool.

Histograms showing the numbers and percent of observation points at which vascular plants were present provide a simple illustration of the relationship between mean annual water depth at a station and the presence or absence of vascular plants. Figure 12 shows the total number of observations at each 0.5-ft depth interval and the numbers of observations of plant occurrence at each interval. Because the number of observations differed among depths, the frequency of plant presence was normalized to the number of observations at each depth, resulting in the depth distribution expressed as percentages in Figure 13. When the observations at which plants were present are considered as a percentage of all observations at a given depth interval (Figure 13), the analysis shows that vascular plants were present at 50 percent or more of the observations of 0.5–7.5 ft adjusted depth. Vascular plants most often occurred at less than 7.5 ft adjusted depth and were only rarely present at depths greater than 9 ft (adjusted depth). The apparently high percentage of vegetation presence at intervals 17 and 22.5 in Figure 13 reflects the low number of total observations at these depths. Vegetation observed at depths greater than 13 ft was consistently very low density (e.g., one stem).

The logistic regression, which considers both observations of presence and absence of vegetation, suggests that water depth affects vegetation presence ( $P < 0.05$ ; Table B-1 and

Figure 14). The logistic regression equation can be used to predict the probability that vegetation will be present at a given depth (Table 1). For example, at depths greater than 15 ft, the probability that vegetation will occur is  $\leq$  5 percent. The quantile plot of the distribution of each relative density of vegetation against depth (Figure 15) shows that the density of vegetation also changes with increasing depth, with only low density vegetation present at depths greater than about 11.5 ft adjusted depth and high density vegetation limited to adjusted depths of 9 ft or less.

Two-way classification tables of each sediment size category and each vegetation density indicate that plants were increasingly less likely to be present when larger sediment size categories or wood was present (Table 2). These tables list the number of times in the data set that each density class of plants was observed in the presence of each sediment size class. For example, in fine sediments, a high density of vegetation was present 188 times, out of a total of 1,238 observations of fine sediments. In only 12 observations of high plant density fine sediments were not observed. In total, 543 of 1,238 (44 percent) observations in which fine sediments were present, plants were also present. In contrast, a high density of plants was present in only 13 out of 289 (4 percent) observations in which cobble was present.

On the basis of the two-way classification tables, it would be expected that sediment size would be predictive of the presence/absence or density of vegetation. However, the predictive contributions of the sediment size variables to the logistic regression model could not be assessed because the resultant models were highly unstable. The instability of models in which sediment size was considered was due to the high degree of correlation between sediment size classes (Table 3). Nonetheless, the two-way classification tables show that fine sediments supported plant assemblages more often than any other sediment type and that plants occurred in the presence of all substrate sizes and types at least occasionally.

Additional analysis of this data will be preferred to determine if river flow velocity at a given location, which may correlate to grain size and sediment type, correlates to the occurrence of vegetation.

## **FOOD WEB ANALYSIS AND COMMUNITY STRUCTURE**

---

One objective of this study is to characterize the relative value of specific vegetated habitat types to aquatic biota such as macroinvertebrates, fish, and waterfowl. Several lines of investigation to support characterization of habitat value are discussed in the Study Plan. To conduct the investigation, it was necessary to collect replicate samples for analysis of biological parameters from habitat patches that were representative of two specific vegetated habitat types, *T. natans* and *V. americana*, and unvegetated areas. Selection of specific sampling locations that were representative of habitat conditions for collection of PMI, BMI, sediment, and fish community samples, and fish tissue samples for PCB analysis, is discussed below. Fish community characteristics and qualitative observations of BMI and PMI communities are presented in later sections.

### **STATION LOCATIONS**

Exponent personnel visited Thompson Island Pool and Stillwater on August 13 and September 11, 1997, to select sample station locations. The second site visit included personnel from NYSDEC, the National Oceanic and Atmospheric Administration, and EPA. Representatives from these agencies were consulted to determine the locations of previous agency-sponsored fish sampling for PCB monitoring. One station in unvegetated habitat, one in *T. natans*, and one in a representative density of *V. americana* were located in northern Thompson Island Pool (away from Griffin Island), near Griffin Island, and in the vicinity of Stillwater. The only exception was that *T. natans* was absent from the northern Thompson Island Pool area. Therefore, there are only two *T. natans* stations, one in Stillwater and one in the west channel of Griffin Island. Station locations were recorded using DGPS.

The locations of each sampling station are presented in Figures 16 and 17. State plane coordinates and station names are presented in Appendix C. Station names are encoded as two letters representing the location (ST - Stillwater; GI - Griffin Island; and TI - northern Thompson Island Pool), and two letters representing the habitat type (VA - *V. americana*; TR - *T. natans*; UN - unvegetated). These stations are presented in this report to indicate the locations of sampling conducted in support of the fish community analysis (below), and will be discussed in later reports of the results of invertebrate, sediment and fish sampling for analysis of PCBs.

## FISH COMMUNITY ANALYSIS

### Background

The analysis of fish communities provides one of the quantitative measures of habitat value in Thompson Island Pool. Fish community data were also collected at Stillwater for comparison of fish communities between Stillwater and Thompson Island Pool, which may help explain possible differences in food web structures between these locations. Assessment of the fish community in each habitat contributes to a better understanding of the following specific issues discussed in the Study Plan:

- Ecological values associated with vegetated habitats, including relative species biomass and size composition of fishes within the major types of vegetation, between vegetated and unvegetated habitats, and between northern Thompson Island Pool, Griffin Island, and Stillwater.
- Whether the areas sampled by NYSDEC for monitoring PCBs in fish tissue are representative of other habitats and communities in Thompson Island Pool.
- Differences in biological community structure (fish and macroinvertebrates) and associated PCB pathways between dominant vegetation types.
- Potential for habitat modifications as a result of dredging and the influence of dredging on the fish communities that use vegetated habitats.

### Methods

Fish communities in SAV were sampled using buoyant pop-nets (Figure 18). Six pop nets were designed and built with modifications to the design of Serafy et al. (1988). Pop nets consisted of two square frames of white polyvinyl chloride conduit that was painted black, attached to continuous, 6.35-mm nylon mesh netting (Figure 18). Pop nets were 2 m on each side and 2-m deep. The total sampling area of each pop net was 4 m<sup>2</sup>. Sample volume varied depending on the depth of water at the time the net was triggered, with a maximum volume of 8 m<sup>3</sup>. The top frame of the net was made buoyant with aerosol foam, and the lower frame was weighted with a 0.95-cm steel rod and had a 35.6-cm-wide skirt surrounding the edge.

Nets were set in patches of vegetation or in unvegetated habitats with the assistance of divers. Patches were selected to represent the average density of the plant species for the general area. *T. natans* occurs almost exclusively at high densities; medium density *V. americana* was selected as the representative density of that plant species. In the set position, both frames were clasped together with a pin and collar hardware unit (or

trigger) attached to a small loop of rope, and the entire net was placed on the river bottom. The skirt was spread around the perimeter of the net to prevent the escape of any fish and to keep external vegetation from getting tangled in the net. The triggers were connected to 10.7-m black ropes that were attached to a floating buoy. In *V. americana* and in unvegetated habitat, an anchor was attached to the buoy to prevent it from floating over the top of the pop net. An anchor was unnecessary in *T. natans* because the dense floating leaves prevented the buoy from moving. These ropes were pulled to release the triggers and allow the buoyant frame to rise to the water surface. The buoyant upper frame rose at a rate of approximately 0.6 m/sec. Nets were set in the afternoon and allowed to equilibrate overnight. Triggers were released on all pop nets during the morning between 7:30 and 10:00 a.m. After the nets were triggered, the vegetation was removed. Fish samples were collected using a backpack electroshocker to shock the fish and dip nets to remove the fish from the pop net. Fish were identified to species using Smith (1985), and their weights and lengths were measured.

Consistent with the field sampling plan (PTI 1997a), pop-net sampling was conducted until three pop-net samples from representative densities of each habitat (*T. natans*, *V. americana*, and unvegetated) in each area (Thompson Island Pool, Griffin Island, and Stillwater) had been successfully obtained. If more than three pop-net samples were successfully obtained in any one habitat, only the three that were completed first chronologically (referred to below as the qualifying pop-net samples) were included in the comparisons of species richness between areas and between habitats, because species richness may be correlated with sample numbers at small sample sizes. All pop nets were considered in calculations of mean standing stock biomass. Results of all pop-net samples are reported in Appendix D. *T. natans* was sampled only at Griffin Island and Stillwater because there was insufficient *T. natans* habitat present in northern Thompson Island Pool in which to collect the full suite of samples.

Fish biomass was calculated as the sum of wet weight mass of all fish caught in each pop net. Standing stock biomass was calculated as the total fish biomass divided by the area of the pop-net frame. Catch per unit effort (CPUE) is the number of fish caught per pop net. Comparisons of these parameters between habitat types and between areas were made using the Mann-Whitney U-test.

Sampling for analysis of PCBs in tissue of largemouth bass, brown bullhead, and pumpkinseed was conducted using a boat electroshocker. The results of the PCB analyses have been presented in a separate data report (PTI 1998). However, because the boat electroshocker was able to cover large areas within specific habitats, non-target fish collected incidentally during electroshocking provide insight into the fish communities characteristic of each habitat. Incidental catch from electroshock sampling was tabulated and summarized according to feeding habits.

## **Results and Discussion**

### **Comparison Between Habitats**

The full results of all pop-net samples are presented in Appendix D. Table 4 is a summary of the results of the pop-net samples, grouped by habitat. Only six qualifying pop-net samples were collected in *T. natans* habitat, and nine qualifying pop-net samples were collected in each of the other two habitats. As a result, comparison of total species number between habitats is limited because total species number could be correlated with total number of samples collected. Nonetheless, it is notable that *V. americana* had the greatest species richness of all habitats, with nine species appearing in the nine qualifying pop nets. Even if only the first six chronological pop-net samples in *V. americana* are considered, the first six samples of *V. americana* still produced six species whereas the first six *T. natans* samples had four species and unvegetated habitat had two species. Pop-net samples from unvegetated habitats rarely produced fish, with seven out of nine samples in unvegetated areas producing no fish at all, and the remaining two samples producing one fish each.

The mean ( $\pm$ S.D.) standing stock biomass of fish in pop-net samples in *T. natans* was 2.6 ( $\pm$ 3.1) g/m<sup>2</sup> (0–8.8 g/m<sup>2</sup>), in *V. americana* was 2.5 ( $\pm$ 2.9) g/m<sup>2</sup> (0–8.7 g/m<sup>2</sup>), and in unvegetated habitats was 0.1 ( $\pm$ 0.2) g/m<sup>2</sup> (0–0.75 g/m<sup>2</sup>). The relatively high standing stock biomass of *V. americana* habitat as a whole can be attributed to the presence of a 27.8 g yellow bullhead in Stillwater pop net number 2 (see Table C-1). In general, the fishes caught in *V. americana* habitats were small forage fish, predominantly minnows (Cyprinidae). Mean CPUE in terms of individual fish of all species was highest in *V. americana* at 6.7 ( $\pm$ 7.7) fish/sample. The second highest was in *T. natans* at 4.9 ( $\pm$ 7.5) fish/sample, and the lowest was in unvegetated habitat at 0.2 ( $\pm$ 0.4) fish/sample. Pairwise comparisons using the Mann-Whitney U-test showed both vegetated habitats to have significantly ( $P < 0.05$ ) greater standing stock biomass and CPUE than unvegetated habitats, but there was no significant difference in these two parameters between the two vegetated habitats. When all sites were grouped within areas, however, CPUE and standing stock biomass may vary significantly between vegetation types, but samples sizes were too small for statistical tests.

### **Comparison Between Areas**

The cumulative number of species in pop-net samples at Stillwater was six, and five species were present in nets at both Griffin Island and Thompson Island Pool. Species number at Griffin Island and Stillwater samples cannot be compared with those of Thompson Island Pool because only six pop-net samples (three in each of two habitats) were obtained from Thompson Island Pool. Mean CPUE for all fish was not significantly ( $P < 0.05$ ) different between Griffin Island, Stillwater, and Thompson Island Pool at 3.9 ( $\pm$ 6.8), 4.8 ( $\pm$ 7.6), and 1.7 ( $\pm$ 3.2), respectively. Mean ( $\pm$ S.D.) standing stock biomass of fish

calculated from all pop-net samples was 1.7 ( $\pm 2.9$ ) g/m<sup>2</sup> (0–8.8 g/m<sup>2</sup>) at Griffin Island and 2.2 ( $\pm 2.9$ ) g/m<sup>2</sup> (0–8.7 g/m<sup>2</sup>) at Stillwater, with the Stillwater biomass value again biased by the presence of the one large yellow bullhead (Figure 19). Pairwise comparisons between areas showed a statistically significant difference in standing stock biomass only between Griffin Island and Stillwater, probably because of the yellow bullhead at Stillwater. The mean ( $\pm$ S.D.) standing stock biomass in Thompson Island Pool was 0.51 ( $\pm 1.0$ ) g/m<sup>2</sup> (0–2.6 g/m<sup>2</sup>), but *T. natans* habitat, which had the greatest standing stock biomass and CPUE in the other two areas, was not sampled in Thompson Island Pool. *V. americana* had the greatest standing stock biomass of habitats sampled at Stillwater and Thompson Island Pool, and *T. natans* had the greatest standing stock biomass of habitats sampled at Griffin Island.

### Comparison With Other Studies

Hankin and Schmidt (1992) measured fish standing stock biomass in *T. natans* and *V. americana* in Tivoli Bay during 1991. In *V. americana* habitat, Hankin and Schmidt (1992) reported 0.3–7.1 g/m<sup>2</sup> fish standing stock biomass in pop nets, with a mean of 3.5 g/m<sup>2</sup>. Pelczarski (1990) reported up to 10.4 g/m<sup>2</sup> and a total of 10 species in *T. natans* but did not report a mean biomass. Few species caught in the present study were also observed by Hankin and Schmidt (1992) and by Pelczarski (1990), but these previous studies were conducted in tidal habitats of the lower Hudson River and differences in critical habitat factors (e.g., tidal fluctuations, presence of anadromous species) determined the fish communities observed.

### Observations of the Fish Community from Electroshock Samples

In electroshock samples (Table 5), 28 species were observed in *V. americana*, 24 species were observed in *T. natans* habitat, and 15 species were observed in unvegetated areas. However, because the fishing effort was different between the three habitat types, the differences in species number could simply reflect the different amount of time spent electroshocking. Gill nets were used at Stillwater to catch fish targeted for PCB analysis; none of the gill net samples had species of fish not caught previously in electroshock samples, but larger sizes of several species were only found in gill nets. Electroshock samples of fish from *T. natans* at Stillwater were collected along the edge of the *T. natans* bed, where *V. americana* was present in medium to high densities. The particular species present in the Stillwater *T. natans* samples and the relatively high number of species there may be due to the proximity of *V. americana* habitat to the electroshock samples. As in pop-net samples, electroshock samples from *V. americana* habitat in all areas were the most species-rich among habitat types, and Stillwater was the most species-rich of the three areas, but this could be due to greater sampling effort in that area. Higher fish species richness suggests a higher degree of trophic complexity in *V. americana* habitats than in other habitats, and in Stillwater relative to other areas.

The fish observed in electroshock samples (Table 5) were classified according to feeding behavior as generally predaceous (one that consumes fish, large invertebrates, amphibians, and occasional birds and mammals), insectivorous, planktivorous, or benthivorous based on diet information provided by Smith (1985; Tables 6 and 7). Because adult fish often have a different diet than juveniles of the same species, a species was counted in all of its possible feeding groups when feeding group totals were calculated for each sampling area.

When the relative abundance of each feeding group is compared between habitats (Table 8); *V. americana* had the most consistent distribution of feeding groups between areas; planktivorous species dominated the collection, present at a rate of 33–38 percent. Planktivores were also dominant in *T. natans*, but the relative abundances of the feeding groups in *T. natans* was more dissimilar between Stillwater and Griffin Island than that of *V. americana*. Unvegetated areas had the highest relative abundance of general predators and very few benthic feeders, except in northern Thompson Island Pool. Griffin Island showed more differences in fish communities between habitats than did Stillwater. Griffin Island *T. natans* had a larger proportion of planktivores and insectivores than did Griffin Island *V. americana*, and less than 10 percent benthic feeders. Communities across habitats in Stillwater were similar, although planktivores were relatively high in unvegetated habitats and benthic feeders were scarce.

## QUALITATIVE OBSERVATIONS OF BMI/PMI

The quantitative analytical results of the BMI and PMI samples are not yet available. Observations of BMI and PMI in the field include the following:

- There were fewer taxa of PMI associated with *V. americana* than with *T. natans*.
- Periphyton was common on all vegetation, but is particularly abundant on *V. americana* throughout Thompson Island Pool and seemed to be more abundant on *V. americana* than on *T. natans*.
- Dominant taxonomic groups in *V. americana* samples were molluscs, chironomids, and amphipods. Samples of PMI from *T. natans* were variable, but amphipods, molluscs, odonates, chironomids and other dipterans, hemipterans, and coloapterans were present in most samples.
- Very few benthic invertebrates were found, especially in sediments from northern Thompson Island Pool and Griffin Island. BMI included chironomids, molluscs, and oligochaetes.

The ongoing analysis of invertebrate samples includes identification and enumeration of all species present in each sample. Results are expected to be available in the first quarter of 1998 and will allow determination of food web complexity and comparisons between

habitats. Taxonomy of PMI and BMI samples, in combination with the results of the fish stomach content analyses, will also be used to interpret feeding patterns of forage fish.

## **INTERIM STUDY CONCLUSIONS**

---

The information summarized in this interim data report partially addresses the potential for habitat modification as a result of dredging and the influence of dredging on the fish communities that use vegetated habitats. The results of the vegetation survey indicate that a significant area of the main channel of Thompson Island Pool is vegetated, primarily by *V. americana* and secondarily by *T. natans*. Medium to high density growth of vascular plants in Thompson Island Pool is generally restricted to waters that, on the basis of average flow conditions, are less than or equal to approximately 10 ft deep (Figure 15). Plants are found rarely and only in very low densities at depths greater than 11.5 ft.

A qualitative analysis of the relationship between the presence of SAV and sediment characteristics indicates that SAV is most commonly associated with fine sediments in Thompson Island Pool. In the river margins, where current velocities are lowest, fine sediments become deposited and remain in place because of an absence of scouring action. The river margins, which are also the shallowest part of the channel, allow for significant light penetration, creating a generally hospitable environment for aquatic plant growth. In addition, fine sediments usually have a high TOC content, and as a result are generally the most contaminated with PCBs of all sediment types in an aquatic system. These sediments, which support a large fraction of the total plant biomass observed in this study, have been the target of past dredging proposals to remove PCB-contaminated sediments from the Upper Hudson River. Because vegetation density appears to be a function of water depth, increases in water depth resulting from sediment removal will reduce the vegetation density. Based on the analysis of the presence or absence of plants as a function of water depth, deepening of the channel to greater than approximately 9–10 ft (on the basis of average flow conditions) as a result of sediment removal will result in the loss of vegetation in these areas.

Pop nets were used in this study because they provide quantitative samples of fish communities in vegetated aquatic habitats better than other fish sampling techniques (Serafy et al. 1988). Although pop-net samples do not fully describe a fish community associated with a particular habitat type, their replicability and the quantitative nature of pop-net samples allows direct comparison of fish communities between habitats, between individual pop nets, and between sampling areas. Fish communities sampled in *V. americana* habitats are the most species-rich among habitat types. On the basis of standing stock biomass and CPUE, vegetated habitats have significantly more fish than unvegetated habitats, but are not significantly different from each other when all stations for a habitat type are grouped. Differences between habitats within areas were not tested due to small sample sizes. With the level of replication in this study, the variability is high for CPUE and biomass, which is consistent with qualitative observations made during sampling and during previous studies that used the same sampling method (Hankin and Schmidt 1992). CPUE standing stock and fish species numbers in *T. natans* were comparable to those in

*V. americana*. Samples from unvegetated areas had very few fish, suggesting that unvegetated areas are relatively poor habitat for fish.

The communities of fish represented by the full set of pop-net samples in each area were very dissimilar with only pumpkinseed common to samples from all three areas. The differences between areas in the assemblage of species present, species richness, and biomass in quantitative (i.e., pop-net) samples, and the variation in these parameters suggests that no one area is "representative" of either of the other two with respect to the forage fish community. Moreover, on the basis of fish species number, *V. americana* may have a more complex food web, especially in Stillwater. The differences in relative abundances of feeding groups between habitats at Griffin Island indicates a high potential for variability in the food web at Griffin Island relative to Thompson Island Pool and Stillwater. Although invertebrate diversity appeared to be high in *T. natans*, suggesting longer food chains there, the variation in the relative abundance of fish feeding groups in *T. natans* makes it difficult to generalize about biomagnification potential on the basis of the existing data.

Sediment removal would deepen the shallow areas that support growth of aquatic plants and increase the extent of unvegetated habitat. These results indicate that, to the extent vegetation supports more species, greater numbers, and more biomass of fish, a sediment removal program that increases water depth to greater than 10 ft (based on annual average flow) would reduce the most extensive fish habitats in Thompson Island Pool. Habitat loss would negatively impact the fish community, and the bird and mammalian predators that rely on the food web in this habitat, by reducing fish biomass and numbers of fish species for every year that the habitat is absent or poorly restored. The total fish biomass that would be lost can be estimated on the basis of the data presented in this report if the area of dredged habitat and the resulting depth are known.

TABLE 7. DIETS OF NEW YORK FISHES\*

Species	Diet
<b>Anguillidae</b>	
American eel ( <i>Anguilla rostrata</i> )	Insects, fish, crustaceans
<b>Atherinidae</b>	
Brook silverside ( <i>Labidesthes sicculus</i> )	Adult and larval surface-dwelling insects, cladocerans
<b>Catastomidae</b>	
White sucker ( <i>Catostomus commersoni</i> )	Benthic invertebrates
<b>Centrarchidae</b>	
Black crappie ( <i>Pomoxis nigromaculatus</i> )	Insects, fish
Bluegill sunfish ( <i>Lepomis macrochirus</i> )	Insects, plant material
Largemouth bass ( <i>Micropterus salmoides</i> )	Insects, fish
Pumpkinseed ( <i>Lepomis gibbosus</i> )	Insects, amphipods, molluscs, smaller fish and amphibians
Redbreast sunfish ( <i>Lepomis auritus</i> )	Plankton, invertebrates
Rock bass ( <i>Ambloplites rupestris</i> )	Highly variable bottom and midwater; plankton copepods and cladocera, insects; fish, crayfish at larger sizes
Smallmouth bass ( <i>Micropterus dolomieu</i> )	Insects, crayfish, fish, tadpoles, and frogs
<b>Clupeidae</b>	
Blueback herring ( <i>Alosa aestivalis</i> )	Copepods, fish larvae, pelagic shrimp larvae
<b>Cyprinidae</b>	
Bluntnose minnow ( <i>Pimephales notatus</i> )	"Bottom ooze" (algae), chironomids, cladocera
Brassy minnow ( <i>Hybognathus hankinsoni</i> )	Algae, cladocerans, copepods, some insects
Carp ( <i>Cyprinus carpio</i> )	Algae and benthic invertebrates
Cutlip minnow ( <i>Exoglossum maxillingua</i> )	Benthic invertebrates (insects and molluscs), detritus and algae
Emerald shiner ( <i>Notropis atherinoides</i> )	Zooplankton, algae/diatoms
Fallfish ( <i>Semotilus corporalis</i> )	Algae and plankton (as juveniles); insects, fish (as adults)
Golden shiner ( <i>Notemigonus crysoleucas</i> )	Algae and zooplankton (adults eat small fish)
Lake chub ( <i>Couesius plumbeus</i> )	Zooplankton, insects, algae, small fish
Rosyface shiner ( <i>Notropis rubellus</i> )	Insects
Spotfin shiner ( <i>Notropis spilopterus</i> )	Insects
Spottail shiner ( <i>Notropis hudsonius</i> )	Zooplankton, benthic invertebrates

## INTRODUCTION

This report presents the results of navigational support for a preliminary study in the Hudson River in upstate New York. The goals of the navigation effort were to provide positioning and navigation for a visual survey with underwater video equipment and for placement and positioning of station location markers for subsequent sediment, aquatic plant, and fish sampling. The navigator and navigation equipment for this preliminary study were provided by David Evans and Associates, Inc. (DEA), Portland, Oregon between August 4 through August 13, 1997.

An integrated and automated hydrographic system was used for positioning and data acquisition. This system consisted of the following instruments: Trimble 4000SE Differential Global Positioning System (DGPS) receiver, Trimble Probeacon Radio for reception of differential broadcasts from the Canadian Coast Guard Beacon, Omnistar National DGPS receiver radio and Coastal Oceanographics Hypack navigation and data acquisition software running on a 486 PC.

### Vessel Positioning

Sub-meter positioning was accomplished with the DGPS system by utilizing differential corrections from the Canadian Coast Guard (CCG) Beacon, Station 312, located at St. Jean-sur-Richelieu (latitude 45° 19.2796' N, longitude 73° 18.6199' W). The CCG shore-based DGPS receiver calculated and transmitted real-time differential corrections to the shipboard DGPS roving receiver at a rate of once per second. Differentially corrected North American Datum (NAD) 83 latitude and longitude values were output every second from the ship DGPS receiver to the data acquisition computer. Using HYPACK software and a three parameter Molodensky transformation, NAD27 New York State Plane East Zone coordinates (U.S. survey feet) were computed and recorded in real-time by the navigation and data acquisition computer. The positioning system was checked by placing the GPS antenna over National Geodetic Survey (NGS) First order control station "Ft. Miller" and inputting published coordinates into the ship's navigation software. The navigation computer displays the difference between assigned coordinates and the current position of the GPS antenna. The resultant deviation recorded at this position check point was 1-foot.

### Methodology

In order to achieve the goals of the study, the crew ran transects from bank to bank, stopping every 20 feet for visual confirmation of the vegetation in the river via underwater video equipment. At every stopping point the navigator would record a position by marking a target to a digital file. The target pinpoints coordinates of the area within 3 feet. The navigator would accompany the target with a description of time and depth in daily logs. These daily logs were also recorded on a 486 PC and backed up daily on disk for post-processing and editing. This technique allows the navigator to know the distance from the last target and locate the next inspection station. Further, the navigator may recall and navigate back to any target with submeter accuracy.

## Hydrographic Equipment

### POSITIONING SYSTEM:

Differential Global Positioning System (DGPS) composed of the following:

- Trimble 4000 SE ship receiver for processing differential positions and outputting geographical coordinates to the ship's processing and data acquisition system.
- Trimble Probeacon radio for reception of the Canadian Coast Guard DGPS Beacon.
- Accuracy for this system is less than 1 meter (1-2 feet typical).

### NAVIGATION:

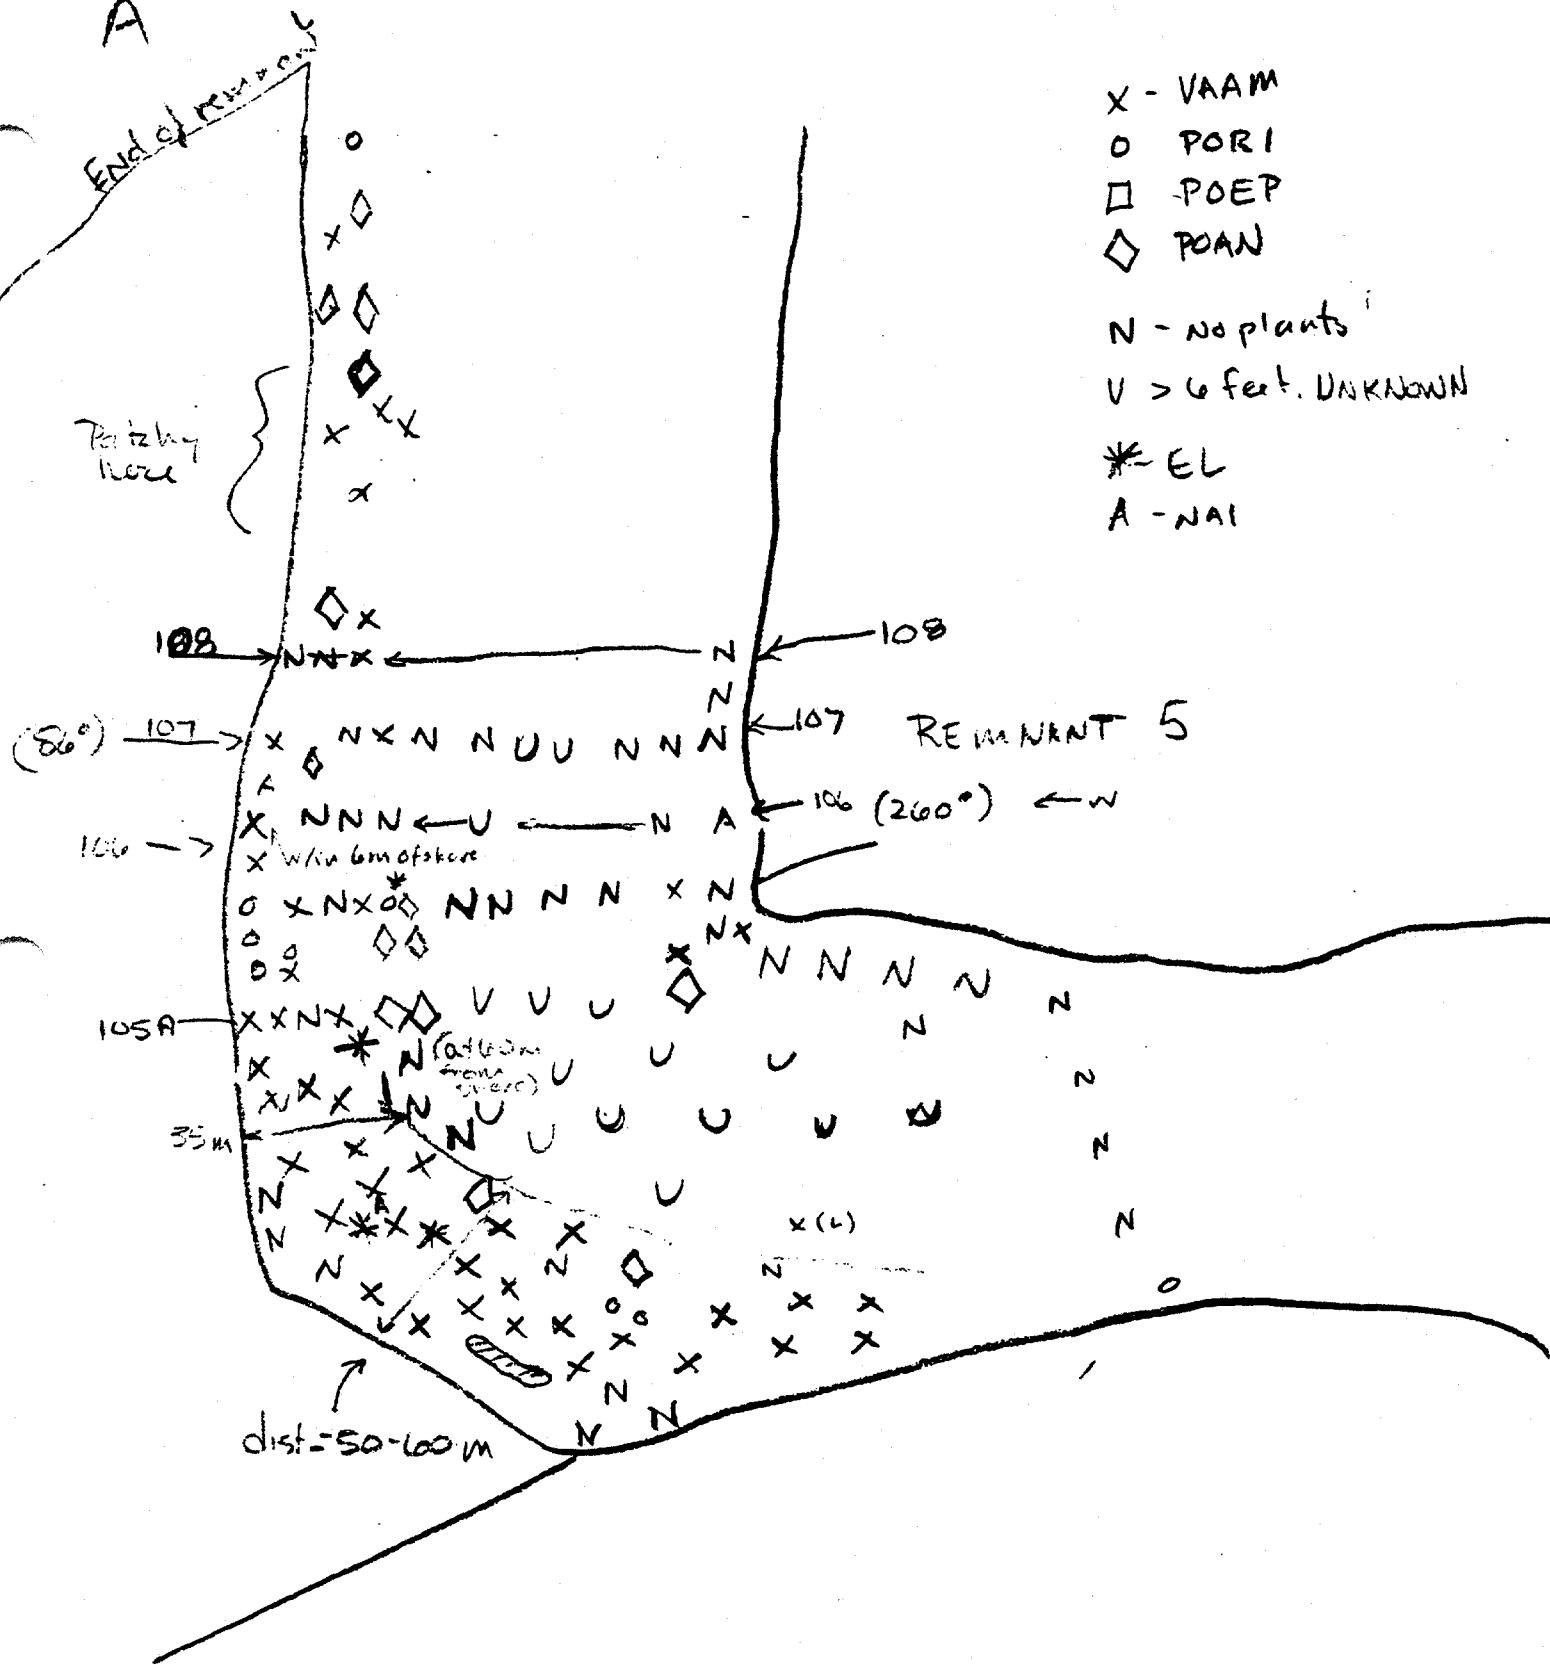

- 486 PC computer with Coastal Oceanographics "HYPACK" software. This system processes geographical positions from the positioning system, provides navigation displays and time tags and records position data.

## Deviations From Scope

At the start of the survey, it was assumed differential corrections would be obtained from the Omnistar National GPS System. The system went down for improvements during the start of the survey and an alternate method was utilized to receive differential corrections. A backup system which included a Trimble Probeacon radio for reception of U.S. Coast Guard (USCG) differential corrections was deployed. This was not the primary system as there is no USCG DGPS stations in the area of operations. The Probeacon radio was set to automatic mode to enable frequency scanning to locate a source of differential corrections. A signal lock was acquired and differential corrections were obtained from a Canadian Coast Guard Beacon. This beacon, Station 312, is located about 230 miles north of the study area in St. Jean-sur-Richelieu, Canada. The beacon provided solid coverage for most of the survey area. Intermittent reception of the DGPS broadcast was a problem in the vicinity of Roger's Island due to the canyon-like terrain and the long range between the CCG beacon and the ship receiver.

T104	B	8/10/97	10:51			5	A												F	S	G			
T104	C	8/10/97	10:51			4	M			V	AM			PR					F	S	G	C	W	R
T104	D	8/10/97	10:53			5	A												F	S				R

Note: NR - not recorded

<sup>a</sup> Vegetation density: A - absent, L - low, M - medium, H - high, N - not seen.

<sup>b</sup> Vegetation species: PA - *Potamogeton angustifolism*, PE - *Potamogeton epihydrus*, V - *Vallisneria americana*, N - *Najas* sp., AM - periphyton, FA - filamentous algae, EL - *Elodea canadensis*, PR - *Potamogeton richardsonii*, NY - *Nymphaea odorata*, TR - *Trapa natans*, PV - *Peltandra virginica*.

<sup>c</sup> Sediment observations were qualitative, but sediments were characterized approximately according to the following criteria:

- F - fine ≤ 0.5 mm
- S - sand 0.6–2.0 mm
- G - gravel 2.1–15.0 mm
- C - cobble > 16 mm
- W - wood woody material of all sizes
- R - rock large rocks or bedrock

<sup>d</sup> An unknown plant species was observed at point T11.

T124C	694696.98	1191870.06	T139A	694650.61	1192786.08

<sup>a</sup> Coordinates for T1 through T104 were determined onsite using DGPS. Coordinates for T105 through T139A were determined by digitizing observation points from a hand-drawn map.

## **Appendix B**

### **Output of Logistic Regression**

**TABLE B-1. LOGISTIC REGRESSION OUTPUT (SYSTAT)**

**B0 = Intercept**

Iteration	Parameter	
	Loss	Values
0	.1038585D+04	.1000D+00
1	.9942931D+03	-.3912D+00
2	.9942915D+03	-.3912D+00
3	.9942915D+03	-.3942D+00
4	.9942915D+03	-.3942D+00

Dependent variable is

P - vegetation presence

Final value of loss function is

994.291

Parameter	Estimate	A.S.E.	Lower	<95%>	Upper
B0	-0.394	0.062	-0.515		-0.273

**B1 = depth**

Iteration	Loss	Parameter Values	
0	.1496558D+04	.1000D+00	.1000D+00
1	.9351304D+03	.8896D-01	-.4355D-01
2	.8520577D+03	.1330D+01	-.1634D+00
3	.7808159D+03	.2027D+01	-.3460D+00
4	.7757215D+03	.2191D+01	-.3462D+00
5	.7754980D+03	.2213D+01	-.3435D+00
6	.7754962D+03	.2202D+01	-.3420D+00
7	.7754961D+03	.2204D+01	-.3423D+00
8	.7754961D+03	.2204D+01	-.3423D+00

Dependent variable is

P - vegetation presence

Final value of loss function is

775.496

Parameter	Estimate	A.S.E.	Lower	<95%>	Upper
B0	2.204	0.163	1.884		2.523
B1	-0.342	0.021	-0.384		-0.300

**Asymptotic Correlation Matrix of Parameters**

	B0	B1
B0	1.000	
B1	-0.921	1.000

Difference in values of loss function = 218.795

## **Appendix C**

### **Fish Pop-Net and Macroinvertebrate Station Coordinates**

**TABLE C-1. NEW YORK STATE PLANE  
COORDINATES OF FISH POP-NET AND  
MACROINVERTEBRATE SAMPLING STATIONS**

Station ID <sup>a</sup>	X Coordinate	Y Coordinate
STTR	688664.47353	1075779.06540
STUN	686956.53962	1073210.38977
STVA	684261.11707	1071720.11604
GIUN	699754.78118	1167240.77937
GIUD	699801.20033	1167516.59994
GITR	699705.11045	1168155.64945
GIVA	701090.09595	1170857.27978
TIUN	695766.87928	1182812.31484
TIVA	696043.58543	1183333.15552

<sup>a</sup> The station names are coded as follows:

The first two letters designate the area

- GI - Griffin Island
- TI - Northern Thompson Island Pool
- ST - Stillwater

The second two letters designate habitat type, as follows:

- TR - *Trapa natans*
- VA - *Vallisneria americana*
- UD - unvegetated deep water
- UN - unvegetated.

## **Appendix D**

### **Pop-Net Data**

**TABLE D-1. RESULTS OF ALL POP-NET SAMPLES**

Area <sup>a</sup>	Station Habitat <sup>b</sup>	#	Total Fish	Date Popped	Time Popped	Species Name	Wet Weight (g)	Length (mm)

<sup>a</sup> The station names are coded as follows:

- GI - Griffin Island
- TI - Northern Thompson Island Pool
- ST - Stillwater

<sup>b</sup> The habitat types are coded as follows:

- TR - *Trapa natans*
- VA - *Vallisneria americana*
- UN - unvegetated.

<sup>c</sup> Not a qualifying pop-net sample. Qualifying pop-net samples were the first three chronological samples from successful pop nets. Although STUN6, STVA4, and STTR4 were valid samples, they were not included in comparisons of fish communities because they were "extra." Only the first three pop-net samples at each station were included in comparisons in the text of this report.
