## Appendix C

# Derivation of Particulate Emission Factor for ATV Riding

## 1.0 Introduction

One pathway that humans may be exposed to contaminants in soil is by inhalation of particles of soil that become re-suspended in air. When reliable site-specific measurements of contaminant levels in air due to re-suspended soil particles are not available<sup>1</sup>, the concentration of contaminants may be estimated as follows (U.S. Environmental Protection Agency [EPA] 1996, 2002):

$$C_{air} = C_{soil} \cdot PEF$$

where:

|            |   |                                                              |
|------------|---|--------------------------------------------------------------|
| $C_{air}$  | = | Concentration of contaminant in air (mg/m <sup>3</sup> )     |
| $C_{soil}$ | = | Concentration of contaminant in soil (mg/kg)                 |
| $PEF$      | = | Soil to air particulate emission factor (kg/m <sup>3</sup> ) |

Note, the particulate emission factor (PEF) term in this equation is the inverse of the value presented in EPA (1996, 2002), which has units of m<sup>3</sup>/kg.

The value of the PEF depends on a number of site-specific factors, such as soil conditions (e.g., soil moisture, vegetation cover, presence of rocks, soil type), as well as the nature of the soil disturbance activity (wind, mechanical disturbance) that leads to soil particle re-suspension in air. The following sections present the derivation of the PEF value used to estimate contaminant concentrations in air from the re-suspension of soil attributable to riding all-terrain vehicles (ATVs).

## 2.0 Estimation of the PEF

Site-specific data on particulate emissions during ATV riding were collected in the fall of 2018 in accordance with (EPA 2018a, 2018b). The ATV activity-based sampling (ABS) was conducted with single operators on two ATVs driven on the Alpine Loop within the confines of the Site and a remote roadway while the operators wore appropriate PPE in accordance with the governing SAP. The first ATV was the leader and the second ATV rider was the follower. The follower maintained a safe following distance, similar to what would be expected under normal ATV riding conditions (i.e., as if the operators were not wearing respirators). The distance between ATVs

---

<sup>1</sup> Site-specific measurements of contaminant levels in air due to re-suspended soil particles are available for ATV guides because samples from the entire Alpine Loop within the Site were collected in the fall of 2018. However, recreational ATV rider risk is evaluated based on all roadways at the Site, not just the Alpine Loop; therefore, it is necessary to predict air concentrations while riding outside the Alpine Loop.

depended on the terrain and amount of dust generated by the lead ATV; the following distance was less than 50 yards under less dusty conditions and was as much as 200 yards under very dry, dusty conditions. ATVs were operated at appropriate speeds depending on terrain and safety considerations. SKC-brand personal air samplers with cyclones were attached to each ATV to obtain the respirable dust (e.g., 4 microns); the intakes for these samplers were placed near the breathing zone of the ATV operator. Roadway soil and ATV ABS air samples were collected throughout the Alpine Loop and along remote location off of the Alpine Loop (on and near County Road 4). Site conditions during the sampling include the following:

- Roadways consisted of hard-packed soil with exposed bedrock, roadways are not graded/maintained with the exception of maintaining a stable shoulder.
- Wind speeds averaged about 8 miles per hour on both ATV ABS sampling days.

The PEF for ATV riding was estimated by taking the mean concentration in air generated during ATV use and dividing by the mean soil concentration for the corresponding roadways traversed during the ABS activity. This calculation is as follows:

$$PEF_{atv} = C_{air} / C_{soil}$$

where:

|             |   |                                                                    |
|-------------|---|--------------------------------------------------------------------|
| $PEF_{atv}$ | = | Particulate emission factor for ATV riding (kg/m <sup>3</sup> )    |
| $C_{air}$   | = | Concentration in air based on respirable dust (µg/m <sup>3</sup> ) |
| $C_{soil}$  | = | Concentration in roadway soil (µg/kg)                              |

For this evaluation, the PEF was calculated using air and soil data for manganese. This was because other metals analyzed in the ATV ABS air samples were either not detected, not selected as chemicals of potential concern, or lacking inhalation-specific toxicity information. It is not anticipated that release of metals in dust to air would be chemical-specific; thus, the manganese-specific PEF can be applied to all metals. When calculating the PEF, focus was also placed on the following rider because air concentrations for the leader were often non-detect. Use of a follower-specific PEF will provide conservative estimates of air concentrations for a leader rider. The detailed analytical results used to compute the PEF are presented in **Attachment 1**.

PEF values were calculated separately for both the Alpine loop and the remote location based on the inputs presented in **Table C-1** below. Based on these inputs, the resulting PEF for ATV riding is estimated to be 5.6E-07 kg/m<sup>3</sup> and 2.0E-07 kg/m<sup>3</sup> for the Alpine Loop and remote location, respectively.

**Table C-1. Inputs Used to Calculate PEF for Recreational ATV Riding**

| Location        | Parameter  | Parameter Definition                    | Value    | Units                    | Notes                                                                          |
|-----------------|------------|-----------------------------------------|----------|--------------------------|--------------------------------------------------------------------------------|
| Alpine Loop     | $C_{air}$  | Concentration in air based on PM10 dust | 0.762    | $\mu\text{g}/\text{m}^3$ | Mean manganese air concentration for following rider from the Alpine Loop.     |
|                 | $C_{soil}$ | Concentration in roadway soil           | 1.35E+06 | $\mu\text{g}/\text{kg}$  | Mean roadway soil concentration for samples from the Alpine Loop.              |
| Remote Location | $C_{air}$  | Concentration in air based on PM10 dust | 0.585    | $\mu\text{g}/\text{m}^3$ | Mean manganese air concentration for following rider from the remote location. |
|                 | $C_{soil}$ | Concentration in roadway soil           | 2.92E+06 | $\mu\text{g}/\text{kg}$  | Mean roadway soil concentration for samples from the remote location.          |

Note, the PEF values for both locations are generally similar (within a factor of 3 of each other). This is expected because the road conditions for the Alpine Loop and the remote location were generally similar. For the purposes of estimating air concentrations for use in the risk calculations, the PEF for the Alpine Loop ( $5.6\text{E}-07 \text{ kg}/\text{m}^3$ ) was selected because it will result in higher predicted air concentrations and, hence, more conservative risk estimates.

#### **Footnotes:**

[a] All samples were non-detect.

[b] Low detection frequency; value shown is the maximum detected concentration.

[c] 95 UCL exceeded maximum concentration; value shown is the UCL.

[d] Samples were not analyzed for this chemical.

[e] One sample was analyzed; value shown is the detected concentration.

\*The EPC values for chromium were assumed to be 10% hexavalent chromium and 90% trivalent chromium.  
 \*\*The EPC value for arsenic represents the time-weighted concentration, adjusted for the soil-specific RBA for waste rock (0.06) and overbank (0.60)

\*The EPC values for chromium were assumed to be 10% hexavalent chromium and 90% trivalent chromium.

\*\*The EPC value for arsenic represents the time-weighted concentration, adjusted for the soil-specific RBA for waste rock (0.06) and overbank (0.60)

Ctissue = game tissue concentration    DI = dietary intake    mg = milligram    RME = reasonable maximum exposure  
Csoil = soil concentration    HIF = human intake factor    NC = non-cancer    SF = slope factor  
CTE = cental tendency exposure    HQ = hazard quotient    RBA = relative bioavailability    NA = not available  
d = day    kg = kilogram    RfD = reference dose    -- = not calculated

\*The EPC values for chromium were assumed to be 10% hexavalent chromium and 90% trivalent chromium.

\*\*The EPC value for arsenic represents the time-weighted concentration, adjusted for the soil-specific RBA for waste rock (0.06) and overbank (0.60)

Ctissue = game tissue concentration      DI = dietary intake      mg = milligram      RME = reasonable maximum exposure  
Csoil = soil concentration                  HIF = human intake factor      NC = non-cancer      SF = slope factor  
CTE = cental tendency exposure          HQ = hazard quotient          RBA = relative bioavailblty      NA = not available  
d = day                                              kg = kilogram                  RfD = reference dose              -- = not calculated

\*The EPC values for chromium were assumed to be 10% hexavalent chromium and 90% trivalent chromium.

\*\*The EPC value for arsenic represents the time-weighted concentration, adjusted for the soil-specific RBA for waste rock (0.06) and overbank (0.60)

Ctissue = game tissue concentration    DI = dietary intake    mg = milligram    RME = reasonable maximum exposure  
Csoil = soil concentration    HIF = human intake factor    NC = non-cancer    SF = slope factor  
CTE = cental tendency exposure    HQ = hazard quotient    RBA = relative bioavailblty    NA = not available  
d = day    kg = kilogram    RfD = reference dose    -- = not calculated

## Screening-Level Acute Risk Evaluation

### 1.0 Introduction

Because acute screening levels are not readily available for evaluating Site media, acute screening levels were derived for lead and arsenic in soil/waste rock based on a camping exposure scenario. Soil/waste rock were evaluated because they represent the majority of exposure for a receptor; exposure to surface water is considered minor relative to solid media exposure. Lead and arsenic were selected for evaluation because soil concentrations are notably elevated at several locations within the mining districts and both are often important human health risk drivers for mining-related contamination. The camping scenario was selected for the derivation of acute screening levels because the camper is anticipated to be the most sedentary of receptors (i.e., not moving about being exposed to a variety of soil/mine waste sources, in contrast with hiker, hunter, fisherman, all-terrain vehicle rider/guide, and road worker receptors). Derivation of screening levels for a sedentary receptor allows for the application of these screening levels to smaller exposure areas, such as individual campgrounds and dispersed areas suitable for camping.

Focus was placed on evaluating acute exposures to children because children are often more vulnerable to pollutants than adults due to differences in behavior and biology that can lead to greater exposure and/or unique windows of susceptibility during development. Additionally, soil ingestion rates for young children are higher than adults due to increased frequency of contact through hand-to-mouth or object-to-mouth activity. Thus, exposure parameters used in the derivation of the acute screening levels were tailored for children two years of age. Two exposure scenarios for a child that may camp within the mining districts were evaluated:

- Scenario 1: Child, based on central tendency exposure (CTE) soil intake rates specific to a camping exposure scenario
- Scenario 2: Child, based on reasonable maximum exposure (RME) soil intake rates specific to a camping exposure scenario

The derivation of, and differences between, exposure estimates for these two scenarios are described further below. Section 2.1 describes the approach for lead and Section 2.2 describes the approach for arsenic.

### 2.0 Derivation and Application of Acute Screening Levels

As noted above, acute screening levels have been developed for two exposure scenarios resulting in a range of acute screening levels for consideration in risk management decision-making. The sections below present the approach and assumptions used in the derivation of the acute screening levels for lead and arsenic for application to soil/waste rock.

Acute screening levels were developed based on exposure durations of 2 days and 14 days. An exposure duration of 2 days represents a camping duration of a weekend, while 14 days represents the maximum allowable time that may be spent camping in one location in the national forest (U.S. Forest Service [USFS] 2018).

## 2.1 Lead

The U.S. Environmental Protection Agency (EPA) recommends the use of the Integrated Exposure Uptake Biokinetic (IEUBK) model to evaluate exposures from lead-contaminated media in children in a residential setting for continuous exposure of sufficient duration to result in a quasi-steady state (EPA 1994). The IEUBK model was not designed to assess short-term (less than 90 days), periodic (less frequent than one exposure per week), or acute (less than or equal to 14 days) exposures (EPA 2016). Because of this, an alternate model was selected to evaluate acute exposure to lead from a short-term camping scenario. EPA has recommended the use of the All Ages Lead Model (AALM) for evaluating short-term exposure scenarios (EPA 2016). The AALM is still in development, however, a beta version (FORTRAN 1.0) of this model is available (upon EPA request) and was used in researching effects of lead exposures at various life stages to support the development of the acute screening levels. The version of the model used to derive acute lead screening levels in this appendix was provided by EPA on November 16, 2018.

The AALM was used to evaluate a “pulse” exposure occurring for either 2 days or 14 days, by a child due to incidental ingestion of soil/waste rock encountered at a specific location (e.g., campground or other suitable area for camping). The model output includes predicted lead concentrations in various body compartments including the blood, plasma, kidney, liver, bone, etc. for specified time step intervals (e.g., daily) with interpolated changes between steps. The AALM was run using a time step of 0.01 days to allow for maximum precision. This output can be used to determine peak blood lead (PbB) concentrations following a pulse exposure.

**Table F-1** presents the general input parameters used to derive the acute screening levels for lead, recognizing that several of the assumptions may differ from those typically used in an evaluation of chronic exposure to lead.

**Table F-1. General Parameters Used to Calculate the Acute Lead Screening Levels**

| Parameter                                   | Value                    | Source                        |
|---------------------------------------------|--------------------------|-------------------------------|
| Target PbB level (µg/dL)                    | 19.5                     | EPA 2016                      |
| Maternal PbB level (µg/dL)                  | 0.6                      | EPA 2017b                     |
| Default drinking water concentration (µg/L) | 0.9                      | EPA 2017a                     |
| Background soil lead concentration (mg/kg)  | 100                      | Site-specific Scribe database |
| Air lead concentration (µg/m <sup>3</sup> ) | 0.10                     | IEUBK default                 |
| Dust lead concentration (mg/kg)             | 0.7 * soil concentration | IEUBK assumption              |
| RBA (dispersed campsite soil)               | 0.54                     | Site-specific average         |
| RBA (waste rock)                            | 0.23                     | Site-specific average         |
| Receptor gender                             | Female                   | AALM model                    |

mg/kg – milligrams per kilogram

PbB – blood lead

RBA – relative bioavailability

µg/dL – micrograms per deciliter

µg/L – micrograms per liter

The rationale for the selection of each input provided in **Table F-1** is presented below:

- Target PbB level – An acute blood lead threshold of 20 micrograms per deciliter (µg/dL) was identified in Office of Land and Emergency Management (OLEM) Directive 9285.6-54, *Recommendations for Assessing Short-term Exposure Involving Lead at Superfund Sites* (EPA 2016). Per EPA (2016), a PbB level of 20 µg/dL could be considered as a short-term elevation in PbB that would trigger a response action. This is based on the interpretation of the Center for Disease Control (CDC) recommendation that PbB levels in the range of 20 to 44 µg/dL would result in a home visit by a public health agency within 24 hours of a referral from a physician (CDC 2012). For the purposes of this evaluation, 19.5 µg/dL was selected as target PbB for establishing an acute screening level, to account for rounding to two significant digits.
- Maternal PbB level – A maternal PbB level of 0.6 µg/dL was selected based the recommendation provided in OLEM Directive 9285.6-56 (EPA 2017b).
- Default drinking water concentration – A default lead drinking water concentration of 0.9 micrograms per liter (µg/L) was selected based the value used in the *Headquarters Lead Consultation Intake Form for the Colorado Smelter Superfund Site* (EPA 2017a).
- Background soil lead concentration – A background soil lead concentration of 100 milligrams per kilogram (mg/kg) was selected based on the mean soil lead concentration measured in upland reference soil collected within the mining districts.
- Air lead concentration – The default outdoor air lead concentration of 0.1 µg/m<sup>3</sup> in the IEUBK model was selected.
- Dust lead concentration – The background dust concentration was assumed to be 70% of the concentration in soil (i.e., 100 mg/kg · 0.7 = 70 mg/kg), as is usually assumed in the IEUBK model.
- Relative bioavailability (RBA) – Lead RBA was determined by measuring in vitro bioaccessability for campsite soil and waste rock samples collected within the mining districts. The mean estimate of RBA for lead was 0.54 and 0.23 for campsite soil and waste rock, respectively. Because of the variability between the mean RBA values for campsite soil and waste rock samples, screening levels were developed for each media type using their respective RBA values.
- Receptor gender – A female receptor was selected because female children have a lower body weight than male children (per default inputs in the AALM). A receptor with a lower body weight is more sensitive to exposure compared to a receptor with a higher body weight.

**Table F-2** presents the scenario-specific input parameters used to derive the acute screening level for lead.

**Table F-2. Scenario-Specific Parameters Used to Calculate the Acute Lead Screening Levels**

| Parameter                                             | Scenario 1<br>CTE Camping | Scenario 2<br>RME Camping | Source               |
|-------------------------------------------------------|---------------------------|---------------------------|----------------------|
| Soil intake rate during pulse exposure (g soil/day)   | 0.367                     | 1.592                     | EPA 2008 (Table 5-6) |
| Soil intake rate prior to pulse exposure (g soil/day) | 0.094                     | 0.094                     | EPA 2017a            |
| Water intake rate (L water/day)                       | 0.51                      | 0.51                      | EPA 2017a            |
| Diet intake rate ( $\mu\text{g Pb/day}$ )             | 5.21                      | 5.21                      | EPA 2017a            |
| Receptor age at first pulse exposure                  | 2 years old<br>(730 days) | 2 years old<br>(730 days) | EPA 2008 (Table 5-6) |

CTE – central tendency exposure

g – grams

L – liters

Pb – lead

RME – reasonable maximum exposure

$\mu\text{g}$  – micrograms

The rationale for the selection of each input provided in **Table F-2** is presented below:

- Soil intake rate during pulse exposure – Soil intake rates were selected for use in the model to present a range of acute screening levels. In each case, the most conservative soil intake rate available for each scenario was selected so that the most sensitive receptor was used in the model.
  - Scenario 1 – The soil intake rate selected for a CTE child while camping was 0.367 g/day because this is the highest geometric mean intake rate provided in the *Child-Specific Exposure Factors Handbook* (EPA 2008, Table 5-6). This value corresponds to a 2-year-old to 3-year-old girl. The study upon which this value is based evaluated soil intake using a tracer element methodology for 78 children aged 1 to 5 years old at campgrounds (Van Wijnen et al. 1990).
  - Scenario 2 – The soil intake rate selected for an RME child while camping was 1.592 g/day because this is the 95<sup>th</sup> percentile (computed using the reported geomean and geometric standard deviation) for the intake rates provided for the 2-year-old to 3-year-old girl (EPA 2008, Table 5-6).
- Soil intake rate prior to pulse exposure – The soil intake rate prior to the pulse selected for use in the model was the soil intake rate provided in the *Headquarters Lead Consultation Intake Form for the Colorado Smelter Superfund Site* (EPA 2017a) for the age group prior to the pulse. The soil intake rate prior to pulse was 0.094 g/day (soil intake rate for a 1-year old to 2-year old).
- Water intake rate – The drinking water intake rate selected for use in the model was 0.51 liters per day (L/day), based the values provided in the *Headquarters Lead Consultation Intake Form for the Colorado Smelter Superfund Site* (EPA 2017a).

- Dietary intake rate – The dietary lead intake rate selected for use in the model was 5.21 micrograms per day ( $\mu\text{g}/\text{day}$ ), based the values provided in the *Headquarters Lead Consultation Intake Form for the Colorado Smelter Superfund Site* (EPA 2017a).
- Receptor age at first pulse exposure – The age at first pulse exposure was 730 days (2 years old).

**Table F-3** presents the acute screening levels for lead based on a 2-day and 14-day exposure to soil/waste rock that were derived based on the inputs provided in the tables above and for the scenarios that have been described. The acute screening levels were derived by determining the soil/waste rock concentration that would result in a predicted peak PbB concentration of 19.5  $\mu\text{g}/\text{dL}$ .

**Table F-3. Acute Lead Screening Levels (mg/kg)**

**Panel A. Dispersed Campsite Soil (RBA = 0.54)**

| Scenario   | 2 Day Exposure | 14 Day Exposure |
|------------|----------------|-----------------|
| Scenario 1 | 2,594          | 1,331           |
| Scenario 2 | 596            | 306             |

**Panel B. Waste Rock (RBA = 0.23)**

| Scenario   | 2 Day Exposure | 14 Day Exposure |
|------------|----------------|-----------------|
| Scenario 1 | 6,090          | 3,125           |
| Scenario 2 | 1,400          | 719             |

mg/kg – milligrams per kilogram

As seen in **Panel A** and **Panel B** in **Table F-3**, the change in screening level is inversely proportional to the change in RBA; decreasing the RBA by a factor of 2.35 increases the screening level by 2.35.

For demonstration purposes, **Figure F-1** presents a graphical display of the predicted PbB concentrations based on the acute screening levels for waste rock developed for a 2-day and 14-day exposure for Scenario 1 (CTE). As seen, the predicted PbB concentrations rise sharply for the 2-day exposure to soils containing 6,090 mg/kg to reach 19.5  $\mu\text{g}/\text{dL}$ . In contrast, the predicted PbB concentrations have a more gradual rise for the 14-day exposure to soils containing 3,125 mg/kg to reach 19.5  $\mu\text{g}/\text{dL}$ .

A comparison of the applicable lead screening levels to data collected from campgrounds and waste rock was performed. The lead soil concentrations used in the evaluation were based on the fine (250- $\mu\text{m}$ ) size fraction. An adjustment factor was applied to estimate the fine fraction from the 2-mm result (EPA 2000, 2017a). The adjustment factor was determined by performing a regression analysis of the lead results for samples sieved to 2-mm and to 250- $\mu\text{m}$ . The regression analysis is presented in Figure 5-1 in the main document. As shown, lead concentrations for the fine fraction were estimated as follows<sup>1</sup>:

<sup>1</sup> In order to be conservative, for cases where the predicted concentration of lead in soil for the fine fraction resulted in a value less than what was measured in the bulk fraction, the concentration in the bulk fraction

$$C_{\text{soil}, 250\text{-}\mu\text{m}} = 1.625 \cdot C_{\text{soil}, 2\text{-mm}} - 226.36$$

where:

$C_{\text{soil}, 250\text{-}\mu\text{m}}$  = Estimated lead concentration in soil for the fine (250- $\mu\text{m}$ ) fraction

$C_{\text{soil}, 2\text{-mm}}$  = Measured lead concentration in soil for the bulk (2-mm) fraction

**Figure F-2** presents the comparison of the applicable lead screening levels to samples collected from campgrounds/dispersed campsites<sup>2</sup> and waste rock. **Panel A** presents the comparison using a linear scale so that the magnitude of exceedances can be observed; **Panel B** presents the comparison using a log scale so that exceedances of screening levels can be seen easier. For the acute risk evaluation, exposure was evaluated for individual samples rather than assume that exposure occurs evenly across an exposure area as was done for the chronic risk evaluation. For campgrounds, the 14-day screening level was selected; for waste rock, the 2-day screening level was selected. Samples collected from waste rock areas are more remote (i.e., less accessible) and are not representative of areas that are frequently used for camping. Concentrations of lead in upland reference soil have also been included for comparison purposes. As seen, there are multiple campground samples with lead concentrations that exceed the 14-day CTE and RME screening levels. Samples collected from dispersed campsites 2, 3, 4, and 7 had the greatest exceedance margin. For waste rock, there were many samples that exceeded the 2-day CTE and RME screening levels. For the upland reference samples, there were a few exceedances of the RME screening level, but no exceedances of the CTE screening level as presented in **Figure F-2**.

## 2.2 Arsenic

Acute toxicity information is generally lacking for arsenic, and acute arsenic screening levels specific to the type of receptors present within the mining districts (i.e., recreational visitors) are not available. A review of *Toxicological Profile for Arsenic* developed by the Agency for Toxic Substances and Disease Registry (ATSDR) reveals oral doses as low as 0.02 to 0.06 milligrams of arsenic per kilogram body weight per day (mg/kg BW/day) have been reported to cause toxic effects in some individuals (ATSDR 1989). Severe exposures can result in acute encephalopathy, congestive heart failure, stupor, convulsions, paralysis, coma, and death. The acute lethal dose to humans has been estimated to be about 0.6 mg/kg BW/day (ATSDR 1989).

Washington State Department of Health (WSDOH) provides a synopsis of published scientific information related to soil exposure and acute toxicity in *Hazards of Short-term Exposure to Arsenic Contaminated Soil* (WSDOH 1999). The most sensitive reported indicators of acute toxicity appear to be edema, conjunctivitis, liver enlargement, irritation of the mucous membranes, and gastrointestinal problems such as vomiting, diarrhea, cramps, and pain. Transient adverse health effects commonly occur when doses between 0.035 and 0.071 milligrams of arsenic per kilogram of body weight (mg/kg BW) are ingested. The best estimate of an acute threshold for transient effects is 0.05 mg/kg BW. Using the acute transient effect dose

---

was adopted. This situation occurs at low concentration levels because the fine fraction and the bulk fraction become approximately equivalent.

<sup>2</sup> A “dispersed” campsite is an area that is suitable for camping or where camping is known to occur but may not be a formal campground.

information, acute arsenic screening levels can be derived for the same two exposure scenarios that were evaluated for lead (see Section 2.1). The equation used to derive the acute arsenic screening level is as follows:

$$ASL_{As} = (ATE / SF) / (IR / CF_{IR} / BW \cdot ED \cdot RBA)$$

where:

|            |   |                                                    |
|------------|---|----------------------------------------------------|
| $ASL_{As}$ | = | Acute screening level for arsenic (mg/kg soil)     |
| ATE        | = | Acute transient effect dose (mg/kg BW)             |
| SF         | = | Toxicity safety factor (unitless)                  |
| IR         | = | Soil intake rate (g soil/day)                      |
| $CF_{IR}$  | = | Conversion factor for intake rate, convert g to kg |
| BW         | = | Body weight (kg)                                   |
| ED         | = | Exposure duration (days)                           |
| RBA        | = | Relative bioavailability                           |

When possible, consistent exposure parameters were used for arsenic and lead. **Table F-4** presents the general input parameters used to derive the acute screening levels for arsenic, recognizing that several of the assumptions may differ from those typically used in an evaluation of chronic exposures.

**Table F-4. General Parameters Used to Calculate the Acute Arsenic Screening Levels**

| Parameter                                               | Value  | Source                |
|---------------------------------------------------------|--------|-----------------------|
| Receptor gender                                         | Female | EPA 2008 (Table 8-10) |
| Acute transient effect dose (mg arsenic/kg body weight) | 0.05   | WSDOH 1999            |
| Toxicity safety factor (unitless)                       | 10     | WSDOH 1999            |
| RBA (disperse campsite soil)                            | 0.07   | Site-specific average |
| RBA (waste rock)                                        | 0.05   | Site-specific average |

mg– milligrams

kg – kilograms

RBA – relative bioavailability

The rationale for the selection of each input provided in **Table F-4** is presented below:

- Receptor gender – A female receptor was selected because female children have a lower body weight than male children (EPA 2008). A receptor with a lower body weight is more sensitive to exposure compared to a receptor with a higher body weight.
- Acute transient effect dose – The best estimate acute transient effect dose was selected to represent the dose at which edema, conjunctivitis, liver enlargement, irritation of the

mucous membranes, and/or gastrointestinal problems (vomiting, diarrhea, cramps, and pain) may occur (WSDOH 1999).

- Toxicity safety factor – A no-effect level is typically estimated by dividing the dose observed to cause health effects by a safety factor. There is little scientific information available to guide the selection of a safety factor for short-term exposure to arsenic in soil. The selection must be based on judgement of the margin of safety desired for protection from the potential adverse consequences of this type of event. For the two scenarios, a safety factor of 10 was considered adequate to estimate a no-effect level from an acute effect level for the purposes of calculating soil arsenic concentrations protective of human health. This choice was based on consideration of documented variability in human sensitivity to the toxic effects of arsenic as well as consideration of likelihood of occurrence of the various scenarios (WSDOH 1999).
- RBA – Arsenic RBA was determined by measuring in vitro bioaccessability for dispersed campsite soil and waste rock samples collected within the mining districts. The mean estimate of RBA for arsenic was 0.07 and 0.05 for dispersed campsite soil and waste rock, respectively. Screening levels were developed for each media type using their respective RBA values.

**Table F-5** presents the scenario-specific input parameters used to derive the acute screening level for arsenic.

**Table F-5. Scenario-Specific Parameters Used to Calculate the Acute Arsenic Screening Levels**

| Parameter                                     | Scenario 1<br>CTE Camping | Scenario 2<br>RME Camping | Source                |
|-----------------------------------------------|---------------------------|---------------------------|-----------------------|
| Soil intake rate during exposure (g soil/day) | 0.367                     | 1.592                     | EPA 2008 (Table 5-6)  |
| Receptor age at exposure                      | 2 years old               | 2 years old               | EPA 2008 (Table 5-6)  |
| Receptor body weight (kg)                     | 12.5                      | 12.5                      | EPA 2008 (Table 8-10) |

CTE – central tendency exposure

g – grams

kg – kilograms

RME – reasonable maximum exposure

The rationale for the selection of each input provided in **Table F-5** is presented below:

- Soil intake rate during pulse exposure – Similar to the approach for deriving acute screening levels for lead, multiple soil intake rates were selected for use in the calculations to present a range of acute screening levels. In each case, the most conservative soil intake rate available for each scenario was selected so that the most sensitive receptor was used in the calculations. The soil intake rates used for arsenic are the same as those selected for lead during the pulse exposure. See Section 2.1 for the basis of the selected soil intake values for each scenario.
- Receptor age at exposure – Similar to the approach for deriving acute screening levels for lead, the age at exposure was 2 years old.

- Receptor body weight – The receptor body was selected to correlate to the age and gender of the receptor. The mean female body weight for a 2-year old was selected (EPA 2008, Table 8-10).

**Table F-6** presents the acute screening levels for arsenic based on a 2-day and 14-day exposure to soil/waste rock that were derived based on the inputs provided in the tables above and for the scenarios that have been described.

**Table F-6. Acute Arsenic Screening Levels (mg/kg)**

**Panel A. Dispersed Campsite Soil (RBA = 0.07)**

| Scenario   | 2 Day Exposure | 14 Day Exposure |
|------------|----------------|-----------------|
| Scenario 1 | 1,216          | 174             |
| Scenario 2 | 280            | 40              |

**Panel B. Waste Rock (RBA = 0.05)**

| Scenario   | 2 Day Exposure | 14 Day Exposure |
|------------|----------------|-----------------|
| Scenario 1 | 1,703          | 243             |
| Scenario 2 | 393            | 56              |

mg/kg – milligrams per kilogram

RBA – relative bioavailability

As seen, the change in screening level is inversely proportional to the change in RBA; decreasing the RBA by a factor of 1.4 increases the screening level by 1.4.

Review of the available campsite and waste rock data for arsenic was performed. **Figure F-3** presents a comparison of the applicable arsenic screening levels to samples collected from campgrounds/dispersed campsites and waste rock. **Panel A** presents the comparison using a linear scale so that the magnitude of exceedances can be observed; **Panel B** presents the comparison using a log scale so that exceedances of screening levels can be seen easier. For the acute risk evaluation, exposure was evaluated for individual samples representative of individual campgrounds rather than assume that exposure occurs evenly across campsites within an exposure area as was done for the chronic risk evaluation. Similar to the acute evaluation for lead, the 14-day screening level was selected for application to campgrounds; for waste rock, the 2-day screening level was selected. Concentrations for upland reference soil samples are also included in **Figure F-3** for comparison to the screening levels. For campground soil samples, concentrations of arsenic do not exceed the CTE screening levels, but there were some locations with soil concentrations greater than the RME screening level. For waste rock, there were four samples (collected from the Koehler Mine, Junction Mine, and Longfellow Mine) that exceeded the CTE screening level and three additional samples that exceeded the RME screening level. For all upland reference soil samples, the concentrations of arsenic observed are below the range of possible screening levels.

### 3.0 Uncertainty Assessment

Similar to the chronic risk evaluation, quantitative evaluation of acute risks to humans from environmental contamination is limited by uncertainty regarding a number of key data items, including concentration levels in the environment, the true level of human contact with

contaminated media, and the true acute effects in humans. This uncertainty is usually addressed by making assumptions or estimates for uncertain parameters based on whatever limited data are available. Because of these assumptions and estimates, the results of the acute evaluation are uncertain, and it is important for risk managers and the public to keep this in mind when interpreting the results of this evaluation. The following sections review the main sources of uncertainty.

### 3.1 Relative Bioavailability

An assumed average bioavailability was used in deriving the screening levels. Sample-specific bioavailability could be either higher or lower. For lead, sample-specific bioavailability was measured at the four campsite locations with the highest lead concentrations. The RBA for these locations ranged from 37% to 59%. Applying a sample-specific bioavailability would not change the conclusion that these locations are above both the 2-day and 14-day screening level.

For arsenic, there were several locations that exceeded the CTE screening level using the average RBA. Because sample-specific RBA information is not available at these locations, it is not possible to determine if use of this information would alter conclusions. With the exception of one sample collected from the Junction Mine, an alternate RBA value would not have the potential to change the conclusions because concentrations of arsenic are significantly above the screening level. If the sample-specific RBA for the Junction Mine were available and the RBA was lower, it would be possible that this sample could be below the CTE screening level.

### 3.2 Background Lead Concentration

The derivation of the lead screening levels required an assumed background concentration for lead in soil. Site-specific measurements of lead in upland reference soil indicate average lead concentrations in the mining districts is 100 mg/kg. Campers that may visit the mining districts may be exposed to soil with concentrations of lead that are higher or lower than this value when they are not visiting the Site (e.g., when they are at their residence) resulting in a different baseline blood lead level than was assumed for this acute evaluation.

### 3.3 AALM Model

The AALM model used to derive the lead screening levels is currently undergoing testing, therefore, screening levels derived using the model could require revision in the future if adjustments are made to the model. However, at this time, this is the best model available to evaluate acute lead exposure. The model incorporates time-varying media concentrations, media intake rates, and relative absorption factors to estimate total inhalation and total ingestion uptakes at each model time step. As part of coding and testing the AALM, a number of datasets were simulated, including adult and childhood datasets used during the original Leggett code calibration and validation. Additional datasets identified during a literature search were also included in coding and testing. Based on these tests, parameters with the AALM were adjusted by the model developers to ensure the best overall fit against all datasets (ICF 2016).

### 3.4 Exposure Assumptions

Screening levels were developed for a range of exposure durations and intake rates. **Figure F-2** and **Figure F-3** present screening levels for campgrounds based on a 14-day exposure and screening levels for waste rock based on a 2-day exposure. Acute exposure duration and soil

ingestion rates are likely to be variable. A camper could spend between 1 to 14 days in one location based on the maximum allowable number of days specified in USFS guidelines (USFS 2018). This exposure duration also considers the annual limit of 14 days for use of Bureau of Land Management land for dispersed camping. This maximum exposure duration combined with RME soil ingestion rates may result in overly conservative screening levels.

## 4.0 Conclusions

The screening levels for lead and arsenic presented in this appendix are to be considered in risk management decision-making within the mining districts. A range of values have been provided based on the understanding there may be differences in the applicable exposure scenario depending upon the type of location being evaluated. Evaluation of the locations from which samples were collected is a critical step in the risk management decision process. For example, the 2-day exposure screening levels may be more applicable to remote areas that are more difficult to access, whereas the 14-day exposure screening levels may be more applicable to dispersed campsites with that are easily accessible. In addition, when applying the screening levels, the physical attributes of the location from which samples have been collected should be considered. For example, samples collected from a steep slope are not representative of areas where camping may occur. Application of the screening levels to these areas would be inappropriate.

### 4.1 Lead

For the camping area soils, there are multiple samples with lead concentrations that exceed the 14-day CTE and RME acute screening levels. Because it may be unreasonable to assume that RME soil ingestion rates, which are specific to a camping scenario, are realistic for 14 days, it may be more appropriate to focus on samples that exceed the CTE acute screening level. Given this consideration, samples collected from dispersed campsites 2, 3, 4, and 7 had the greatest exceedance margin of the CTE screening level.

For waste rock, there were many samples that exceeded the 2-day CTE and RME acute screening levels. However, evaluation of the locations where samples were collected is a critical step in the risk management decision process. When evaluating samples in exceedance of the acute screening levels, the physical attributes of the location from which sample was collected should be considered. For example, samples collected from the steep slopes of a waste pile are not representative of areas where camping may occur. Thus, application of the acute camping screening levels to these areas would be inappropriate.

For the upland reference soils, there were a few exceedances of the RME screening level, but no exceedances of the CTE screening level. This indicates that lead concentration in areas at the Site that are not impacted by mining activities would not pose an acute risk to campers based on “typical” soil ingestion rates. However, if the soil ingestion rate were to be at an RME level for 14 consecutive days, acute risks have the potential to be unacceptable in upland reference areas. Because unacceptable exposures are not expected in unimpacted areas, this further supports the conclusion that the 14-day RME screening level is likely to be overly conservative. This should be taken into consideration during risk management decision-making.

## 4.2 Arsenic

For the camping area soil, concentrations of arsenic do not exceed the 14-day CTE acute screening levels, but there were some locations with soil concentrations greater than the RME screening level. For waste rock, there were four samples (collected from three mining areas, including the Koehler Mine, Junction Mine, and Longfellow Mine) that exceeded the 2-day CTE acute screening level and three additional samples that exceeded the RME screening level. For the upland reference soils, the measured arsenic concentrations are below the range of possible screening levels for all samples.

**FIGURE F-1. EXAMPLE AALM OUPUT DATA – 2-DAY VERSUS 14-DAY EXPOSURE DURATION**  
**Bonita Peak Mining District**

**Panel A. Blood Lead Concentration for a 2-Year-Old Female - Single-Pulse Soil Concentration of 6,090 (2 Days)**

**Panel A. Blood Lead Concentration for a 2-Year-Old Female - Single-Pulse Soil Concentration of 3,125 (14 Days)**

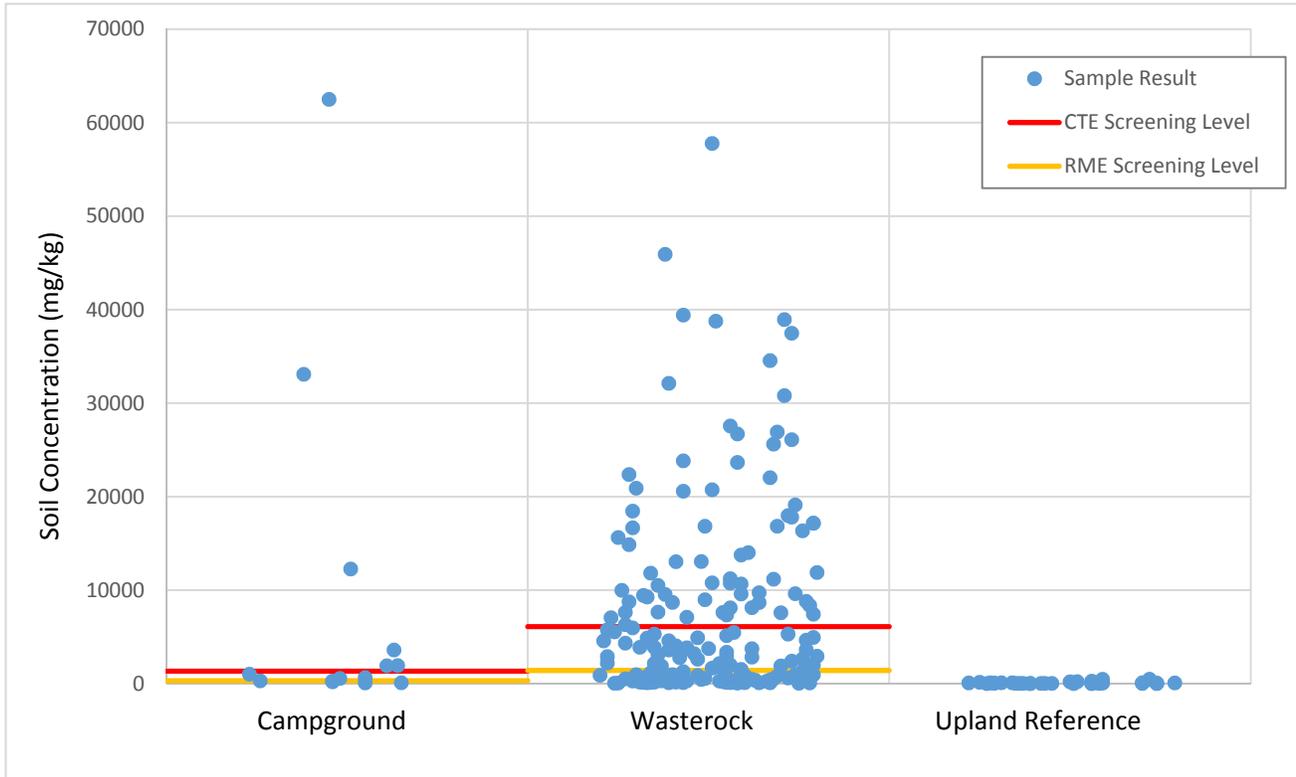

AALM - All Ages Lead Model  
 mg/kg - milligrams per kilogram  
 µg/dL - micrograms per deciliter  
 Cblood - concentration of lead in blood

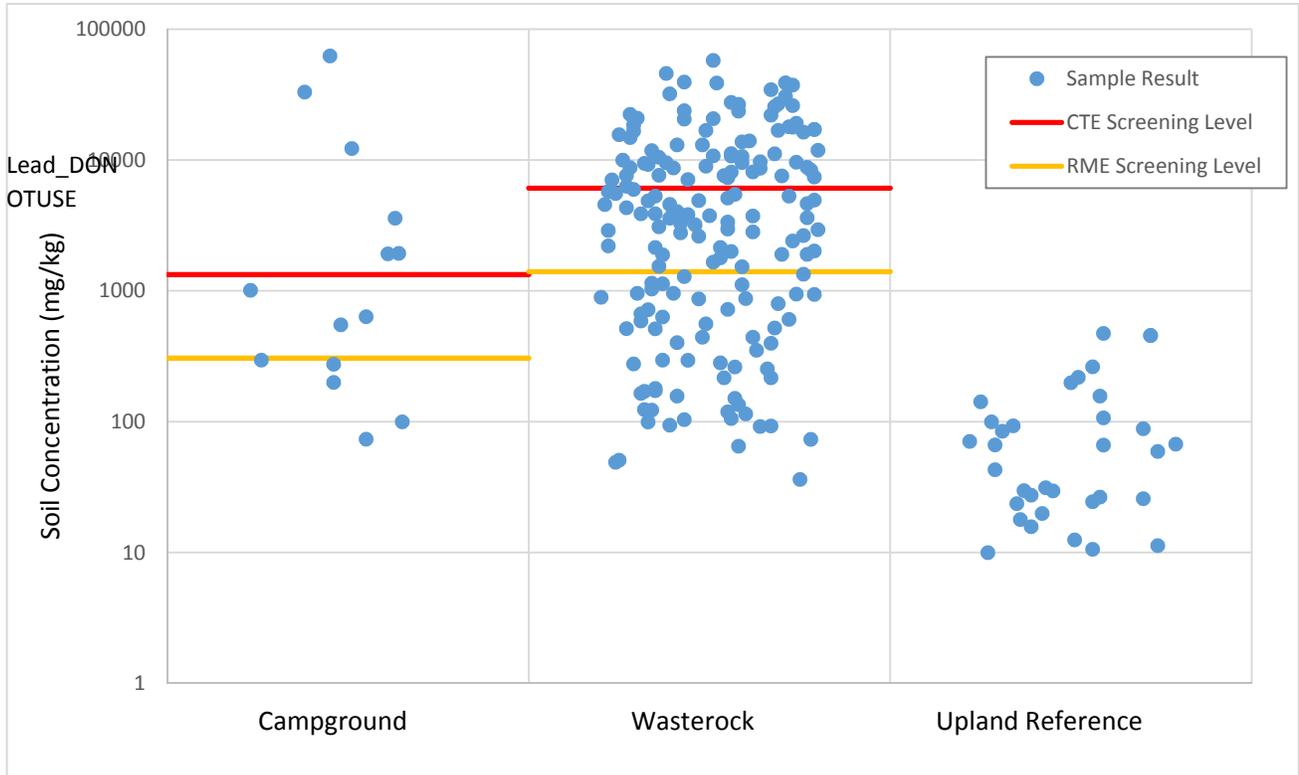

**FIGURE F-2. ACUTE SCREENING LEVEL COMPARISON TO SITE MATERIALS**

**Bonita Peak Mining District**

**Panel A. Linear Scale**

**Panel B. Log Scale**

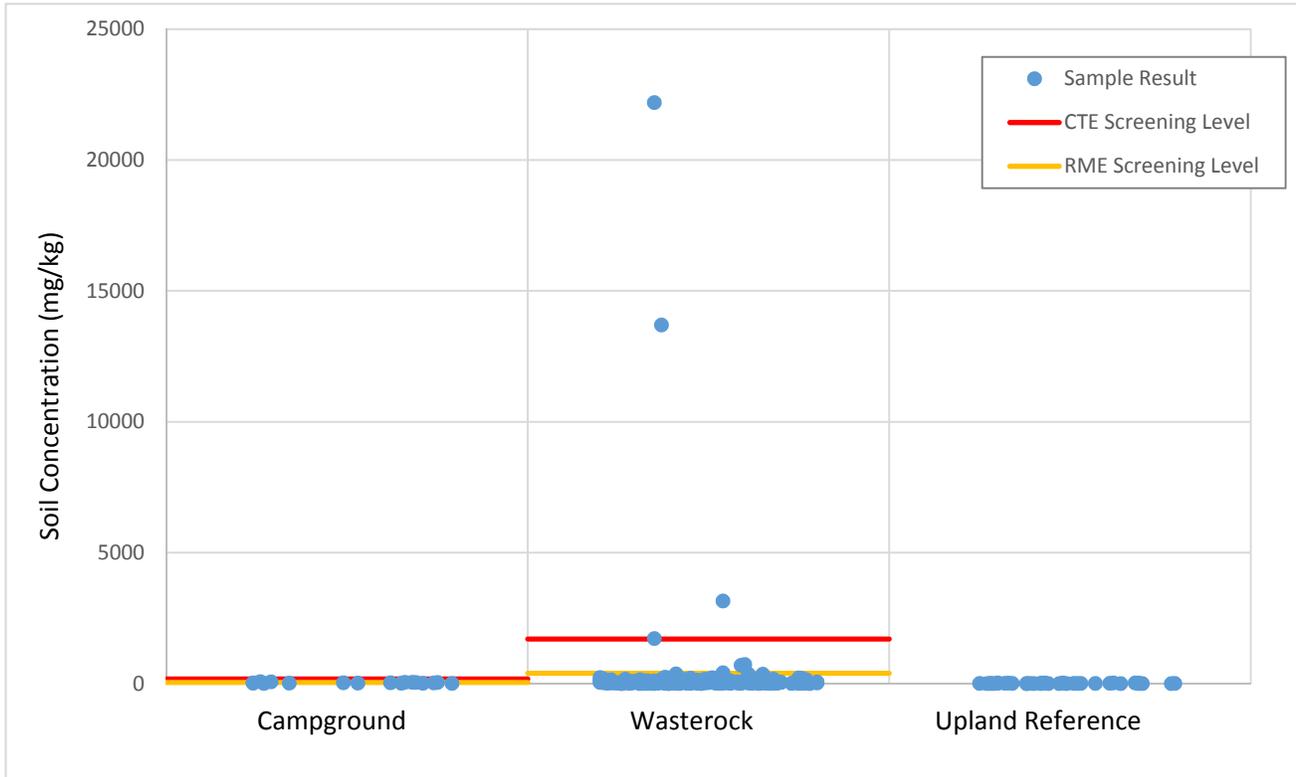

CTE - central tendency exposure  
RME - reasonable maximum exposure  
mg/kg - milligram per kilogram

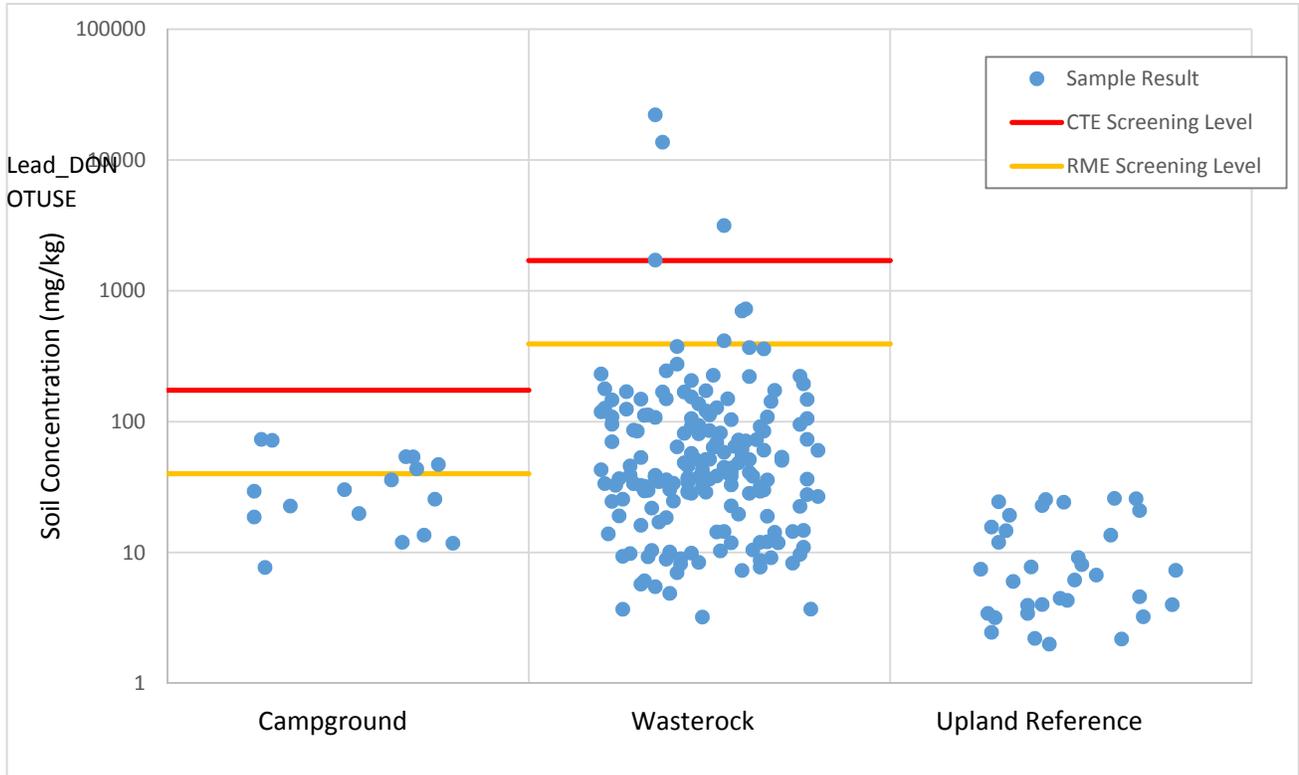

**FIGURE F-3. ACUTE SCREENING LEVEL COMPARISON TO SITE MATERIALS**

**Bonita Peak Mining District**

**Panel A. Linear Scale**

**Panel B. Log Scale**

CTE - central tendency exposure  
RME - reasonable maximum exposure  
mg/kg - milligram per kilogram
